

Effect-size quality control: how much movement is actually being compared?

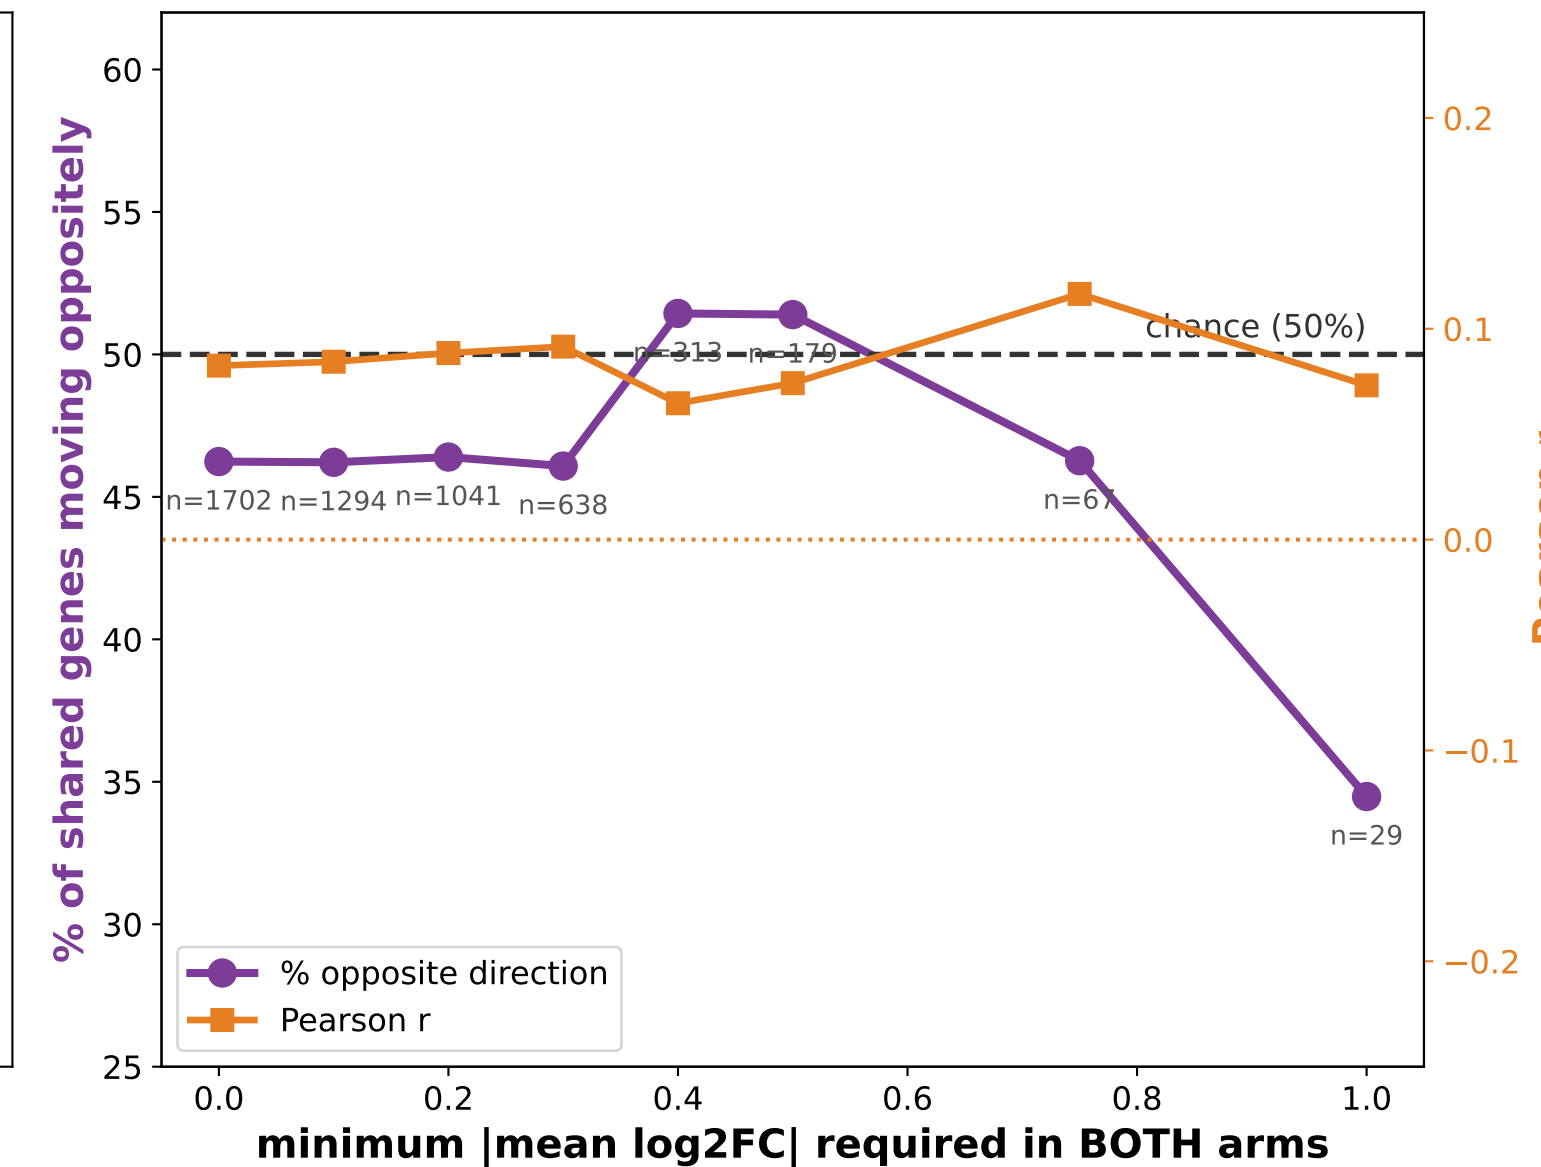

A The GLP-1R arm is compressed
34% of GLP-1R values are below 0.2, vs 7% for HIBI

B Why: cancellation across the 31 GLP-1R groups
genes whose groups disagree average out to ~ 0

C Removing near-zero genes does not reveal a reversal

Near-zero genes are in fact MORE common among discordant genes (19% vs 10% below $|LFC|$ 0.05), so they were inflating the opposite-direction count, not the concordant one.
Direction calls are also unreliable there: vote-direction and $sign(mean)$ disagree for 32% of genes below $|LFC|$ 0.2, versus 7% above 0.5.
